November 16, 2012

PRELIMINARY, PLEASE DO NOT CITE

## Abstract

Utilizing the University of Michigan Survey of Consumer's rotating panel microstructure, we identify whether individuals adjust their inflation expectations over six months. This identification allows us to investigate the updating behavior of individual consumers regarding their short- and long-run inflation expectations. We find evidence that individuals adjust their inflation expectations in line with hypotheses derived from theories of imperfect information. Moreover, individual expectations are found to be more accurate after an update and forecast accuracy is affected by inflation volatility measures and news regarding inflation. Finally, the share of individuals with updated inflation expectations is found to significantly affect spreads in bond markets.

**Keywords:** Rational Inattention, updating inflation expectations, microdata, news.

**JEL classification:** D84, E31.

The authors blame each other for the remaining errors.

# 1 Introduction

Inflation expectations play a central role in modern macroeconomic models and are an important factor for economic policy. Despite their importance, we still know very little about how people form expectations. Researchers have proposed a wide array of frameworks to model the expectations formation process. Contributions by [Sims \(2003\)](#), [Mankiw and Reis \(2002\)](#) or [Woodford \(2001\)](#) revived the interest in information rigidities and its importance for the process of forming inflation expectations. Modeling information rigidities allows to solve several empirical puzzles that did not match the predictions of the full-information rational expectations models, as shown in [Ball et al. \(2005\)](#).<sup>1</sup>

The idea of this paper is to explore the updating behavior regarding inflation expectations of individual consumers using micro survey data. Specifically, we aim at evaluating the updating frequency over time and with regard to the macroeconomic factors that trigger an updating of inflation expectations. In doing so, we test for hypotheses from theories of imperfect information, such as rational inattention as in [Sims \(2003\)](#) or sticky information as in [Mankiw and Reis \(2002\)](#). Furthermore, we analyze which factors influence the individual forecast accuracy and test implications for bond markets.

For our analysis we make use of the rotating panel structure of the University of Michigan Survey of Consumers, where a fraction of individuals is re-interviewed after six months. This allows us to track those individuals and their expectations over a period of six months. From this we can directly calculate the change in individual expectations and the share of individuals that have updated their expectations and, thus, need not to rely on inference coming from the cross section or the aggregated series.

Our paper is related to the literature that analyzes the updating behavior of consumers regarding inflation expectations and tests for evidence of information frictions. For the US, [Carroll \(2003\)](#) finds support for the conjecture of [Mankiw and Reis \(2002\)](#) that consumers update their inflation expectations roughly once a year. Looking at the movements of forecast errors in relation to the variable being forecasted, [Coibion and Gorodnichenko \(2010\)](#) document pervasive and robust evidence consistent with information rigidities and derive a test for information frictions consistent under both sticky information and models of imperfect information as in [Woodford \(2001\)](#). For Europe, [Döpke et al. \(2008\)](#) show that consumers update their inflation expectations once every 18 months.<sup>2</sup> [Lamla and Sarferaz \(2012\)](#) document substantial time-variation in the inflation expectation updating behavior of German households. In sum, these studies provide evidence for staggered updating and for information frictions.

Most of the mentioned papers use aggregate survey data of inflation expectations to test models with informational frictions. However, microdata of individual consumers' inflation expectations may deviate considerably from the aggregate, i.e. the population

---

<sup>1</sup>For an overview see also [Mankiw and Reis \(2011\)](#).

<sup>2</sup>For evidence regarding the expectations updating by professional forecasters, see [Döpke et al. \(2008\)](#).

mean. Recently, studies like [Coibion and Gorodnichenko \(2011\)](#) or [Bachmann et al. \(2011\)](#) have used cross-sectional microdata from the Michigan Survey to discriminate between alternative models of informational rigidities and to test for the link between inflation expectations and reported readiness to spend. In contrast to these studies, we make use the rotating panel dimension of the Michigan Survey of Consumers and, thus, directly track individuals' changes in *individual* inflation expectations *over time* at the micro level. Hence, the use of microdata in conjunction with a dynamic time perspective to analyze the updating of inflation expectations is the main contribution of our paper.

To the best of our knowledge, only very few studies use the rotating panel dimension of the University of Michigan Survey of Consumers. [Souleles \(2004\)](#) employs the rotating panel to construct individual forecast errors, which are then subjected to rationality tests and evaluated with respect to their forecasting power regarding household expenditure. [Pfajfar and Santoro \(2009\)](#) as well as [Anderson et al. \(2010\)](#) analyze differences in the formation of consumers' inflation expectations conditional on sociodemographic characteristics. Very recently, [Pfajfar and Santoro \(2012\)](#) test the hypotheses of the epidemiology model proposed by [Carroll \(2003\)](#).

Our results show that the updating frequency of quantitative inflation expectations, i.e. the point forecasts, is much higher than represented in the aggregate data. We argue that this is likely to be related to the aggregation phenomenon. Moreover, those adjustments are rather small and may be interpreted as some kind of fine-tuning. Substantial adjustments to inflation expectations are conducted on a much lower frequency, which varies strongly over time. In addition, long-term expectations are adjusted less frequently compared to short-run expectations.

Furthermore, we link the updating behavior to models of information frictions, most prominently the concepts of rational inattention and of sticky information, and empirically test for hypotheses derived from those theories. We analyze the updating behavior for short- and long-run expectations and investigate the determinants of forecast errors of individuals also with regard to imperfect information models. We provide evidence in favor of information rigidities showing that measures of volatility of inflation raise attention and consequently trigger an updating of inflation expectations of consumers. In addition, we find support for news effects. If people have heard news on inflation, they are also more likely to adjust their expectations.

Moreover, we find support for an effect of information rigidities on forecast errors at the individual level, where forecast accuracy increases after an update. Finally, individual forecast errors are explained both by the level and the variance of inflation. In line with the hypotheses of imperfect information models, a higher volatility of inflation induces more attention and, thus, is related with better individual inflation forecasts after an update. A surprising result is that individual consumers' forecast accuracy deteriorates with news on inflation, where the effect is driven by news on rising inflation.

Finally, we link the updating of inflation expectations to term spreads in bond markets and find evidence that a higher share of consumers that has updated its expectations corresponds to a larger change in the term spread between 5-year and 1-year treasury bill interest rates as well as between nominal and inflation indexed yields.

The paper is structured as follows. We discuss models with imperfect information in section 2, where we derive our hypotheses for the empirical analysis. In section 3 we discuss the data set used in the analysis. Empirical results regarding the updating behavior of individual inflation expectations and their forecast errors are presented in section 4. Section 5 concludes.

## 2 Theoretical Determinants of Imperfect Information

We start our analysis of individuals' inflation expectations by implementing a simple test for information frictions derived in [Coibion and Gorodnichenko \(2010\)](#). The test is valid under both sticky information or models of information frictions as in the [Lucas \(1972\)](#) island model or in [Woodford \(2001\)](#) and is based on the relation between forecast errors and forecast revisions. It may thus be regarded as a rationality test against the alternative hypothesis of information frictions affecting expectations. [Coibion and Gorodnichenko \(2010\)](#) derive the following formulation for the test equation under sticky information:<sup>3</sup>

$$\pi_{t+h} - E_t^i \pi_{t+h} = \frac{\lambda}{1-\lambda} \Delta E_t^i \pi_{t+h} + \nu_{t+h,t}, \quad (1)$$

where  $\Delta E_t^i \pi_{t+h} = E_t^i \pi_{t+h} - E_{t-1}^i \pi_{t+h}$  is the individual forecast revision,  $\lambda \in [0, 1)$  is the fixed degree of information stickiness and  $\nu_{t+h,t}$  is the rational expectations error. Similarly, under information frictions as in [Lucas \(1972\)](#) and [Woodford \(2001\)](#), agents continuously update their forecasts with a Kalman filter, but underly information constraints and, thus, never obtain the full information set. The relation between forecast errors and forecast revisions is then given by:

$$\pi_{t+h} - E_t^i \pi_{t+h} = \frac{1-G}{G} \Delta E_t^i \pi_{t+h} + \xi_{t+h,t}, \quad (2)$$

where  $G \in (0, 1]$  is the Kalman gain, measuring how much weight is given to new information, and  $\xi_{t+h,t} = \sum_{i=1}^h \rho^i \nu_{t+i}$  is the rational expectations error. Since [Coibion and Gorodnichenko \(2010\)](#) only test for information frictions in aggregate survey data of inflation expectations, we incorporate their test for our analysis of individual microdata and thus get as a first hypothesis:

---

<sup>3</sup>The detailed derivation of the test is given in [Coibion and Gorodnichenko \(2010\)](#).

**H1:** Under imperfect information, individual forecast errors should be a positive function of individual forecast revisions, where the coefficient is bounded above by one.

In order to derive testable hypotheses for individuals' updating behavior, we next present a simple model of inflation expectations under rational inattention. Following the seminal paper by [Sims \(2003\)](#), models of rational inattention assume that individuals are constrained in their capacity to acquire and process information and, hence, may not be able to form full information rational expectations. Nevertheless, some information is observed each period and individuals may choose where to allocate their limited attention.

The structure of the model presented here follows closely the example in [Wiederholt \(2010\)](#), who presents a model of price setting under rational inattention. Since individuals may update their expectations each period, the model can be written as a static problem, omitting time indices. Suppose that the full information rational forecast of inflation,  $\pi^{e,*}$ , is given by:

$$\pi^{e,*} = \theta \Delta, \quad (3)$$

where  $\Delta \sim N(0, \sigma_\Delta^2)$  is a combination of aggregate shocks driving inflation, which is assumed to be normally distributed with mean zero and variance  $\sigma_\Delta^2$ , and  $\theta$  is a parameter. Individuals cannot fully observe  $\pi^{e,*}$ . However, if they choose to pay attention to inflation, they will receive an individual signal  $s_i = \Delta + \varepsilon_i$ , where the idiosyncratic noise  $\varepsilon_i$  is independent from aggregate shocks  $\Delta$  and is also assumed to be normally distributed as  $\varepsilon \sim N(0, \sigma_\varepsilon^2)$ , so that  $s_i$  is multivariate normal. Note that the individual signals  $s_i$  may be interpreted as active searching for information on the part of individuals. Thus, individuals' inflation forecast,  $\pi_i^e$ , can be stated as:

$$\pi_i^e = E[\pi^{e,*} | s_i] \quad (4)$$

Next, the amount of information conveyed in the signal is measured as a reduction in uncertainty. In line with information theory, uncertainty is measured by the entropy of a random variable. In our model with Gaussian shocks, entropy of a random variable  $x \sim N(0, \sigma_x^2)$  is given by:

$$H(x) = \frac{1}{2} \log_2 (2\pi e \sigma_x^2) \quad (5)$$

Similarly, the conditional entropy of  $x$  given the signal  $s_i$  can be written as:

$$H(x|s_i) = \frac{1}{2} \log_2 (2\pi e \sigma_{x|s_i}^2) \quad (6)$$

where  $\sigma_{x|s_i}^2$  is the conditional variance of  $x$  given  $s_i$ . Hence, the amount of information on  $x$  in  $s_i$ , called *mutual information*, is given by the change in entropies conditional on the observation of the signal:

$$I(x; s_i) = H(x) - H(x|s_i) \quad (7)$$

Inflation in our model is driven by aggregate shocks  $\Delta$ , so that we replace  $x$  with  $\Delta$  to get the mutual information in the signals  $s_i$  on inflation shocks  $\Delta$ . When forecasting inflation under less than full information, individuals thus incur a loss, since an inaccurate inflation forecast leads for instance to suboptimal pricing decisions or wage negotiations. Hence, individuals aim at minimizing these losses subject to their information processing constraint. We assume that individuals can choose both the amount of attention  $\kappa$ , paid to inflation at a cost  $\mu$ , and the signals obtained. Additionally, we assume that the marginal cost of an additional unit of attention devoted to inflation is a negative function of news on inflation,  $N$ , perceived by the individual:  $\mu(N)$ . We argue that this effect reflects passive learning about inflation developments, for instance via the exposure to media news, which thus reduces the individual marginal cost of actively searching for information on inflation. Hence, the problem of optimal inattention can be stated as follows:

$$\min_{\sigma_{\Delta|s_i}^2, \kappa \geq 0} E [(\pi_i^e - \pi^{e,*})^2] + \mu(N)\kappa \quad (8)$$

subject to equations (3) and (4),  $s_i = \Delta + \varepsilon_i$  and the information constraint

$$\frac{1}{2} \log_2 (2\pi e \sigma_{\Delta}^2) - \frac{1}{2} \log_2 (2\pi e \sigma_{\Delta|s_i}^2) \leq \kappa \quad (9)$$

From the law of iterated expectations and because the conditional variance of a normal random variable is constant, the objective function can be written in terms of the conditional variance of inflation. Using this result and simplifying, we thus get the following Lagrangian and corresponding first-order conditions:

$$\begin{aligned} \mathcal{L} &= E [\text{Var} (\pi^{e,*}|s_i)] + \mu(N)\kappa - \lambda \left[ \frac{1}{2} \log_2 (2\pi e \sigma_{\Delta}^2) - \frac{1}{2} \log_2 (2\pi e \sigma_{\Delta|s_i}^2) - \kappa \right] \\ &= \theta^2 \sigma_{\Delta|s_i}^2 + \mu(N)\kappa - \lambda \left[ \frac{1}{2} \frac{\ln \sigma_{\Delta}^2}{\ln 2} - \frac{1}{2} \frac{\ln \sigma_{\Delta|s_i}^2}{\ln 2} - \kappa \right] \end{aligned} \quad (10)$$

$$\frac{\partial \mathcal{L}}{\partial \sigma_{\Delta|s_i}^2} = \theta^2 + \frac{1}{2} \lambda \frac{1}{\ln 2} \frac{1}{\sigma_{\Delta|s_i}^2} \stackrel{!}{=} 0 \quad (11)$$

$$\frac{\partial \mathcal{L}}{\partial \kappa} = \mu(N) + \lambda \stackrel{!}{=} 0 \quad \Rightarrow \quad \lambda = -\mu(N) \quad (12)$$

Using (12) in (11) then gives the following expression for the conditional variance of inflation  $\sigma_{\Delta|s_i}^2$ :

$$\sigma_{\Delta|s_i}^2 = \frac{\mu(N)}{2 \ln(2)\theta^2} \quad (13)$$

Finally, substituting for  $\sigma_{\Delta|s_i}^2$  from (13) in the information constraint in (9) gives an expression for optimal attention towards inflation:

$$\kappa^* = \begin{cases} \frac{1}{2} \log_2 \left( \frac{2 \ln(2)\theta^2 \sigma_{\Delta}^2}{\mu(N)} \right) & \text{if } \frac{2 \ln(2)\theta^2 \sigma_{\Delta}^2}{\mu(N)} \geq 1 \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

where the fraction  $(2 \ln(2)\theta^2 \sigma_{\Delta}^2)/\mu(N)$  gives the marginal benefit of paying attention to inflation. From equation (14), we can thus state the next two hypotheses regarding attention towards inflation:<sup>4</sup>

**H2:** Under rational inattention, updates of inflation expectations, i.e. attention towards inflation, should be a positive function of the variance of inflation forecasts under full information  $\theta^2 \sigma_{\Delta}^2$ , which is driven by the variance of aggregate shocks on inflation.

**H3:** Under rational inattention, attention towards inflation should be a positive function of news  $N$  regarding inflation perceived by the individual, since these reduce of the marginal cost  $\mu$  of devoting attention to inflation.

Another approach to implications of imperfect information can be found in Dräger (2011a). In line with the literature on heterogeneous expectations, individuals in the model in Dräger (2011a) may choose between two forecasts of inflation, where one forecast is formed under full information ( $E^{FI}$ ), while the second forecast is formed with outdated (sticky) information ( $E^{SI}$ ). The aggregate expectations index for inflation expectations is then given by:

$$\tilde{E}_t(\pi) \equiv \lambda_t^\pi E_t^{FI}(\pi) + (1 - \lambda_t^\pi) E_t^{SI}(\pi) = \lambda_t^\pi E_t(\pi) + (1 - \lambda_t^\pi) \bar{\lambda} \sum_{j=0}^{\infty} (1 - \bar{\lambda})^j E_{t-1-j}(\pi), \quad (15)$$

where  $\lambda_t^\pi$  is the endogenous and time-varying probability of choosing the full information forecast of inflation. The model thus derives a version of a sticky information model. Moreover, the model also incorporates aspects of rational inattention, since forecasts, and thus information, may change every period. Individuals are assumed to base their decision for a forecast on its forecast performance, measured by the respective squared forecast errors. Additionally, full information can only be obtained at a fixed cost  $C^{FI}$ , which has to be paid each period. Forecast attractiveness is thus given by the expressions:

---

<sup>4</sup>Note that Reis (2006) derives at a similar conclusion regarding the determinants of consumers' optimal degree of inattentiveness in a model with sticky information. However, in contrast to models of rational inattention, the concept of sticky information assumes that forecasts are only updated within fixed intervals, so that the model in Reis (2006) yields in fact the optimal inattentiveness interval.

$$V_t^{FI} = (\pi_{t-1} - E_{t-2}\pi_t)^2 + C^{FI} \quad (16)$$

$$V_t^{SI} = \left( \pi_{t-1} - \bar{\lambda} \sum_{j=0}^{\infty} (1 - \bar{\lambda})^j E_{t-j-3}\pi_t \right)^2 \quad (17)$$

The probability of choosing the full information forecast, given each forecast's attractiveness from equations (16) and (17) is then modelled as a choice of two discrete alternatives under rational inattention. This implies that although individuals have some information on the predictors' accuracy, there remains some uncertainty regarding the optimal forecast or the true values in  $V = (V^{FI}, V^{SI})$ , which may be explained by limitations to the processing of information. As shown in Matějka and McKay (2011), the probability of forecasting inflation with full information is in this case given by a multinomial logit model:

$$\lambda_t^\pi = \frac{\exp(V_t^{FI}/\mu)}{\exp(V_t^{FI}/\mu) + \exp(V_t^{SI}/\mu)}, \quad (18)$$

where  $\mu$  is the cost of a unit of information derived above. From this model, we can thus state the fourth hypothesis regarding attention towards inflation:

**H4:** Under imperfect information and with a choice between costly new information or costless outdated information, attention towards inflation should increase with higher past forecast errors regarding inflation.

### 3 The Data

We analyze microdata from the University of Michigan Survey of Consumers, which is available for the sample period January 1978 to November 2011. Since October 1987, each month a sample of about 500 households is interviewed, where the sample is chosen to statistically represent households in the US, excluding Alaska and Hawaii. Sample sizes before 1987m10 were about 600-1400 interviews per month from 1978m1-1980m2, and about 600-700 interviews per month from 1980m3-1987m9. The monthly telephone survey focuses on respondents' perceptions and expectations regarding personal finances, business conditions and news regarding the economy in general, and macroeconomic aggregates such as unemployment, interest rates and inflation. Furthermore, the survey collects individual and household socioeconomic characteristics.<sup>5</sup>

For the analysis of the dynamics of individuals' inflation expectations, we exploit the fact that the Michigan Survey of Consumers includes a rotating panel: Each month, a randomly determined sub-sample of households is chosen to be re-interviewed six months

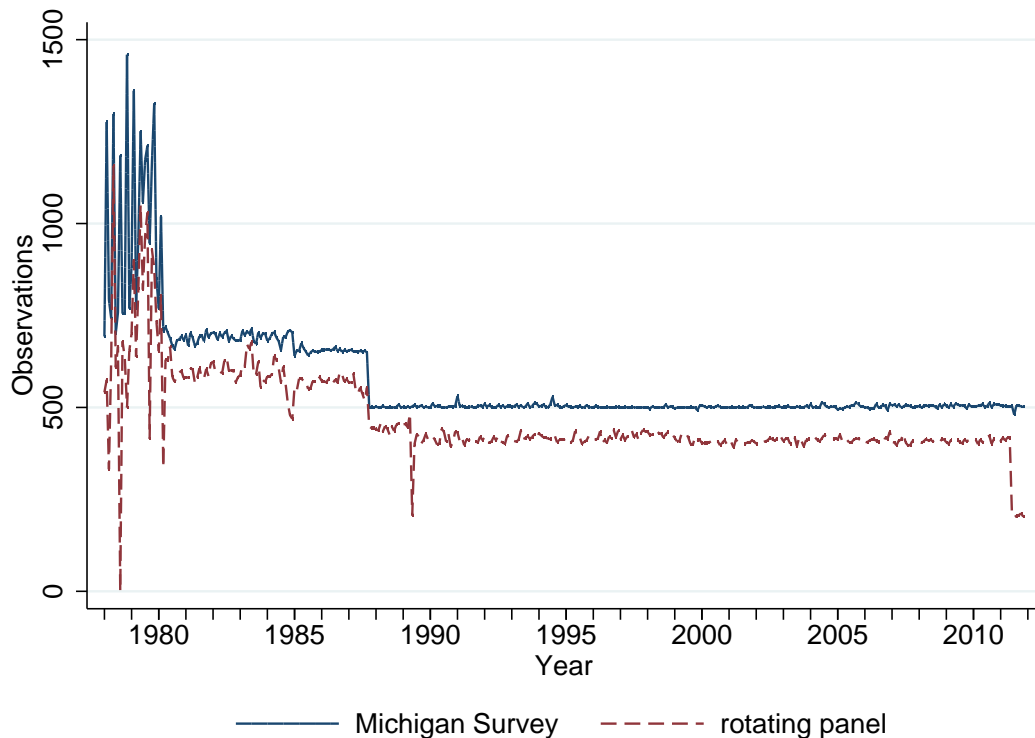

---

<sup>5</sup>For further details on the University of Michigan Survey of Consumers, see <http://www.sca.isr.umich.edu>.

after the first interview. The complete cross-section each month includes about 40% of individuals that are interviewed for the second time. Via the rotating panel structure of the survey, we are able to identify changes in expectations on an individual household level. Figure 1 shows the total sample size of the Michigan Survey of Consumers from 1978 to 2011 and the size of the rotating panel, which includes all households that are interviewed twice, consisting of about 80% (about 400 since 1987m10) of the complete cross-section each month. As shown in Figure 1, sample sizes varied considerably in the earlier months of the survey, and have been relatively constant since October 1987. Consequently, in the following analysis we restrict our sample period to those cross-sections from October 1987 onwards. While this ensures a homogeneous sample size for each cross-section (with very few exceptions) of about 400 individuals each month, we can at the same time exclude any effects from the downward trend in inflation during the Great Moderation.<sup>6</sup>

Figure 1: Identified Cross-Section of Individuals

In order to identify individual changes in inflation expectations at a micro level, we follow Souleles (2004) and Pfajfar and Santoro (2012) and restrict our sample to households where the same person answered both interviews. We thus keep all pairs of observations in the rotating panel, where the interviews were six months apart and where the respondent reported the same sex, race as well as month and year of birth. Additionally, we control for the age of the respondent and only allow increases by one year between interviews. In order to rule out extreme values for inflation expectations, we further truncate our sample

<sup>6</sup>We check for robustness of our results with respect to the sample period chosen and present estimation results for the full sample period upon request.

by excluding the upper and lower 2.5% of the distribution of both short- and long-run quantitative inflation expectations.

For the evaluation of changes in individuals' inflation expectations, we are able to exploit the fact that, in addition to a qualitative question asking about expectations regarding "prices in general", the Michigan Survey includes questions asking for a quantitative estimate of expected inflation. Moreover, the survey allows to distinguish between individuals' expectations regarding inflation during the next year and expectations at a longer horizon of five to ten years. The precise questions of the survey read:

A12. "During the next 12 months, do you think that prices in general will go up, or go down, or stay where they are now?"  
1. GO UP 3. STAY THE SAME 5. GO DOWN 8. DON'T KNOW

A12b. "By about what percent do you expect prices to go (up/down) on the average, during the next 12 months?"

A13. "What about the outlook for prices over the next 5 to 10 years? Do you think prices will be higher, about the same, or lower, 5 to 10 years from now?"  
1. HIGHER 3. STAY THE SAME 5. LOWER 8. DON'T KNOW

A13b. "By about what percent per year do you expect prices to go (up/down) on the average, during the next 5 to 10 years?"

As we are interested in evaluating the role of information frictions for the formation of inflation expectations, we employ the question in the Michigan Survey of Consumers asking for news on the economy heard by the respondent as a measure of perceived news regarding inflation. The wording of the question is as follows:

A6. "During the last few months, have you heard of any favorable or unfavorable changes in business conditions?"  
1. YES 2. NO

If the question is answered with "yes", an open question with two possible answers follows:

A6a. "What did you hear? (Have you heard of any other favorable or unfavorable changes in business conditions?)"

The answers are coded into categories by the Michigan Survey of Consumers. For our purposes, we construct a dummy variable "newsprices" which takes on the value of 1 if the respondent reported news heard on either "*falling prices/deflation*", "*high prices/inflation*", "*higher prices/inflation is good*" or "*lower, stable prices/less inflation*" as either the first

or the second piece of news heard, and zero otherwise. Additionally, we distinguish between news heard about high and low inflation or prices with the dummy variables “newsprices\_high” and “newsprices\_low”. In order to be able to distinguish between favorable or unfavorable news regarding inflation, we further construct the dummy variables “newsprices\_bad” and “newsprices\_good”. We code news on “*higher prices/inflation is good*” and on “*lower, stable prices/less inflation*” as favorably perceived by the respondent, while the other two categories are coded as unfavorable news.

Furthermore, we employ a number of sociodemographic control variables from the Michigan Survey of Consumers in the following analyses, such as age and sex of the respondent as well as income quartiles and a categorical variable measuring education of the respondent in six categories. These are defined as follows: Educ1 – “*Grade 0-8, no high school diploma*”, Educ2 – “*Grade 9-12, no high school diploma*”, Educ3 – “*Grade 0-12, with high school diploma*”, Educ4 – “*4 yrs. of college, no degree*”, Educ5 – “*3 yrs. of college, with degree*” and Educ6 – “*4 yrs. of college, with degree*”.

In addition to the microdata from the Michigan Survey of Consumers, we employ monthly data on actual U.S. inflation since 1978m1 from the FRED database of the St. Louis FED. Monthly data for Treasury-bill constant maturity secondary market rates is also extracted from the FRED database. We further use quarterly data of inflation expectations regarding U.S. inflation from the Survey of Professional Forecasters (SPF), which is available from 1981q3 onwards for one-year-ahead inflation forecasts, and from 1991q4 onwards for ten-years-ahead inflation forecasts. As a measure of cross-sectional dispersion and, thus, as a proxy for professionals’ forecasting uncertainty, we include the interquartile range from the SPF for both one-year-ahead and ten-years-ahead inflation forecasts. Finally, we account for the attention of the media to topics related to U.S. inflation with the number of articles published on U.S. inflation in the New York Times. This measure of external information is obtained from the media research institute MediaTenor and is available on a monthly basis from 1998m1 to 2011m5.<sup>7</sup>

## 4 Results

### 4.1 The Individual Updating Frequency of Inflation Expectations

As a first step, we calculate the share of individuals in each monthly cross-section that adjusted their expectations, denoted as “updating share”. In line with the literature, we interpret the updating share as the share of individuals which updated their information, and, hence, also their expectations. However, it should be noted that in theory it might be possible to update information on inflation and nevertheless keep expectations constant on the basis of new information. While we cannot verify this possibility, we thus note that the updating share represents the lower bound of the monthly number of individuals

---

<sup>7</sup>This data is coded by humans following the standards of media content analysis.

which updated their information regarding inflation. The updating share is calculated for both short- and long-run inflation expectations captured by both the qualitative and the quantitative answers. Summary statistics are given in Table 1.

Table 1: Summary Statistics of the Monthly Updating Shares for Inflation Expectations

Variable	Obs	Mean	SD	Min	Max
Short-run expectations, 1 year	263	0.74	0.05	0.61	0.87
Short-run expectations, 1 year, qualitative answer	263	0.38	0.10	0.16	0.67
Long-run expectations, 5-10 years	231	0.72	0.05	0.57	0.86
Long-run expectations, 5-10 years, qualitative answer	231	0.17	0.05	0.06	0.34

Notes: *Obs* denotes the sample size, *SD* is the standard deviation while *Min* and *Max* represent the minimum and maximum values.

According to our calculations, individuals in the Michigan survey on average update their one-year-ahead inflation expectations based on the quantitative question every 8 months and every 16 months based on the qualitative question. Regarding long-run inflation expectations, the updating frequencies vary between 8 and 36 months based on the quantitative and the qualitative question, respectively. Overall, we find higher updating frequencies using the answers to the quantitative question as reported in the literature from aggregate data.<sup>8</sup> Studies in the sticky information literature employing the population mean of quantitative inflation expectations from U.S. surveys derive an updating share of roughly 0.25 over a quarter, corresponding to 0.5 over six months (Carroll, 2003). This implies that expectations are updated once within a year. A similar result is derived in Döpke et al. (2008) for Europe.

One explanation for our result of a higher updating frequency at the micro level may be related to the aggregation phenomenon. The effect that aggregation of individual data series reduces the variability of the underlying microdata and increases its persistence is a known result, e.g. from movements in price indices (Altissimo et al., 2007).

Notably, the difference in the updating frequency between the qualitative and quantitative answers is quite remarkable. Given the way the questions are phrased, this suggests that individuals fine-tune their quantitative expectations very regularly, but change their general view regarding inflation much less frequently. This implies that qualitative adjustments co-move with substantial adjustments in the quantitative assessment. Alternatively, the high updating share reported from the quantitative question might also be a hint to macroeconomic illiteracy or memory loss (Blanchflower and Kelly, 2008): Some

<sup>8</sup>The Michigan Survey imposes that quantitative inflation expectations be stated as full numbers, excluding decimals. Therefore, an update of quantitative inflation expectations denotes a change of at least one percentage point. Nevertheless, if we impose that an update only be recorded in the event of a change larger than 1 or 5 percentage points, the updating frequency of quantitative expectations is reduced considerably, and the updating share becomes more volatile over time. For summary statistics and graphs of these updating shares, see the Appendix.

individuals might not have changed their view on inflation, but fail to recall the exact number reported six months ago.

To test the hypothesis of fine-tuning, we check whether the mean change in quantitative expectations is smaller if there is no change in the qualitative assessment. For this purpose we employ comparison of mean tests with different variances. Conducting those tests we find support for the hypothesis that quantitative changes are significantly smaller if the qualitative response did not change.<sup>9</sup> This implies that the high updating frequency identified from the quantitative answer represents mainly only very gradual adjustments, where larger adjustments occur when qualitative expectations are adjusted as well.

Long-run expectations are, in line with our expectations, adjusted less often than short-run expectations, particularly qualitative expectations, and hence seem more firmly anchored on average. Long-run expectations should not be affected much by business cycle effects, but rather be related to fundamental factors. Such fundamentals might include the long-run stance of monetary policy, for instance with respect to an inflation target.

Next, we plot the share of households that update their inflation expectations over time together with a smoothing polynomial trend, shown in Figure 2. Several approaches in the literature report evidence that updating shares regarding inflation expectations in the population may vary substantially. Dräger (2011a) argues that people respond to the variance of the forecasted variable, Coibion and Gorodnichenko (2010) show that the information rigidity changes over the business cycle and Lamla and Sarferaz (2012) relate the variation of the updating speed for expectations of German consumers to uncertainty and news effects. Finding time-varying updating frequencies would favor models of rational inattention rather than sticky information, where the updating share of individuals should stay constant over time.

Looking at the changes in qualitative one-year-ahead inflation expectations, we can observe substantial variation in the updating share, varying between about 20% and 60%. Interestingly, we can observe relatively strong surges during recessionary periods. Especially from 2008 onwards, the share of individuals that updated their inflation expectations rose substantially. The cyclical pattern is also present in the updating share from quantitative short-run expectations, albeit less pronounced.

Regarding the updating shares of long-run inflation expectations, we find significantly less time-variation compared to one-year-ahead inflation expectations. Fundamentals and the monetary stance should not change often and hence a rather constant updating share has to be expected. Unfortunately, the question on long-run inflation expectations was not included in every monthly survey before October 1990, leading to missing values in the time series of the updating shares. For the following regression analysis, we thus restrict

---

<sup>9</sup>Test statistics equality of means t-test with unequal variances and with H0: difference of means=0. One-year expectations: t-value=-32.81, Satterthwaite's degrees of freedom=16808, p-value=0.000; test 5-10 years expectations: t-value=-19.79, Satterthwaite's degrees of freedom=3692.68, p-value=0.000

Figure 2: Updating Shares for Inflation Expectations

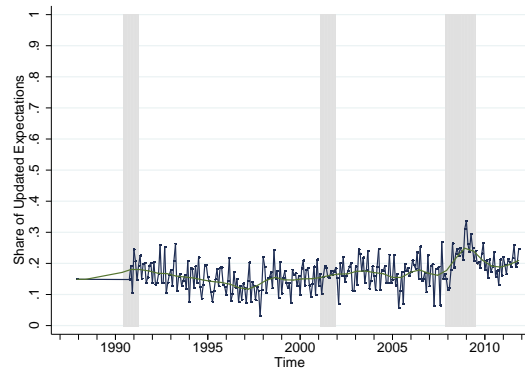

(a) Short-run expectations, 1 year

(b) Short-run expectations, 1 year, qualitative answer

(c) Long-run expectations, 5-10 years

(d) Long-run expectations, 5-10 years, qualitative answer

Notes: The graphs show the share of individual consumers that change their inflation expectations within six months together with a smoothing polynomial trend. Shaded areas are recession phases as identified by the NBER. The share is calculated by taking all individuals that adjusted their expectations during the last six months and divide them by the overall number of individuals that have been re-interviewed.

the sample period for individual long-run inflation expectations to start in October 1990.

## 4.2 Testing for Imperfect Information in Individual Inflation Expectations

After showing that updating shares of inflation expectations vary significantly over time, we next test whether relevant information is incorporated into short-run inflation expectations in the sense that a significant effect of the relevant macroeconomic variables on forecast errors indicates a violation of the rational expectations hypothesis. While most approaches in the literature, for instance [Mankiw et al. \(2004\)](#), regress mean forecast errors on a set of macroeconomic aggregates to test for the rational expectations hypothesis, [Coibion and Gorodnichenko \(2010\)](#) argue that a more concise test for information frictions can be derived as a test for models with information frictions. This is our hypothesis

H1, where in the presence of information frictions, individual forecast errors should be positively affected by the individuals' own forecast revisions. We test this assumption with individual forecast errors from our microdata sample for the period from 1987m10 onwards.<sup>10</sup>

Table 2: Test for Information Frictions with Microdata

	(1)	(2)
	$(\pi_{t+12} - E_t\pi_{t+12})$	$(\pi_{t+12} - E_{i,t}\pi_{t+12})$
$(E_t\pi_{t+12} - E_{t-1}\pi_{t+11})$	0.986 (1.227)	
$(E_{i,t}\pi_{t+12} - E_{i,t-6}\pi_{t+6})$		0.157*** (0.0397)
Constant	-0.737*** (0.1016)	-0.181*** (0.0234)
Observations	281	23,329
Wald $\chi^2(1)$	0.65	15.74
Prob > $\chi^2$	0.421	0.000
Hansen's J $\chi^2(34)$	–	1804.56
Prob > $\chi^2$		0.000
Summary statistics of the first stage		
Adj. $R^2$	0.0267	0.0128
Robust F-stat	6.977	8.415
Prob > F	0.009	0.000

Note: IV regression estimated via GMM. Monthly mean forecast revisions instrumented with the oilpriceshock. Individual forecast revisions instrumented with the oilpriceshock, demographic controls and year fixed effects. Robust standard errors are in parentheses. \*\*\*, \*\* and \* denote significance at the 1%, 5% and 10% level, respectively.  $(\pi_{t+12} - E_t\pi_{t+12})$  is the forecast error, which is explained by the forecast revision based on individual data  $(E_{i,t}\pi_{t+12} - E_{i,t-6}\pi_{t+6})$  and aggregated data  $(E_t\pi_{t+12} - E_{t-1}\pi_{t+11})$ .

Due to the fixed horizon of inflation expectations in the Michigan survey, instead of forecast revisions  $(E_{i,t}\pi_{t+12} - E_{i,t-6}\pi_{t+12})$  between the first and the second interview, we have the individual change in the 1-year-ahead inflation forecast  $(E_{i,t}\pi_{t+12} - E_{i,t-6}\pi_{t+6})$  between interviews. Using this measure as a proxy for individual forecast revisions introduces persistence in the error term. In line with Coibion and Gorodnichenko (2010), we thus instrument for the individual forecast revision with an oilprice shock. Additional instruments include sociodemographic characteristics and year fixed-effects.<sup>11</sup>

Table 2 shows the results of the test for information rigidities from GMM estimates with robust standard errors. It compares estimation results of monthly mean forecast

<sup>10</sup>Results for the whole sample period are available from the authors upon request.

<sup>11</sup>The oilprice shock is derived as in Coibion and Gorodnichenko (2010) using the residual of a regression of nominal oilprice increases on an AR(1) and AR(2) term.

errors with individual forecast errors from the underlying microdata. Hence, the first column is basically a replication of the analysis in [Coibion and Gorodnichenko \(2010\)](#) where forecast revisions are proxied by the change in mean expectations with respect to the previous month, while the second column evaluates individual forecast errors using individual changes in expectations between interviews as a proxy for forecast revisions. In contrast to the findings of [Coibion and Gorodnichenko \(2010\)](#), the coefficient of forecast revisions, albeit positive, is insignificant when using aggregated expectations. This may be due to the slightly differing estimation period and the fact that we use monthly instead of quarterly data. When testing for information frictions directly with the underlying microdata, we find a smaller, but significantly positive coefficient on instrumented forecast revisions, indicating that H1 cannot be rejected. However, this result should be interpreted cautiously as the additional instruments, sociodemographic and year fixed effects, are likely correlated with the error term in the second stage, leading to a rejection of Hansen’s overidentification test. Nevertheless, we argue that they are necessary to account for individual- and time-specific variation.

### 4.3 Updating Inflation Expectations

The general test by [Coibion and Gorodnichenko \(2010\)](#) in the previous section indicated that information frictions may affect individuals’ formation of inflation expectations. In this section, we go one step further and link the updating behavior regarding inflation expectations to possible determinants derived from the theories of imperfect information discussed in section 2. Specifically, we estimate pooled cross-section probit models for the propensity to update both individual quantitative and qualitative short- and long-run inflation expectations in the second interview, including aggregate regressors derived from the theoretic models as well as demographic factors and a dummy variable capturing recession periods as defined by the NBER.

From the simple model of rational inattention regarding inflation derived in section 2, we get our second hypothesis H2, stating that attentiveness towards inflation should be affected by the variance of inflation forecasts under full information, i.e. the variance of actual inflation. This result is also presented in [Maćkowiak and Wiederholt \(2009\)](#) in a rational inattention model of price setting and in [Reis \(2006\)](#) in a sticky information model. In order to test for H2, we thus include both the variability of actual inflation and of professional forecasters’ inflation outlook from the Survey of Professional Forecasters as determinants for the probability of an update of inflation expectations. We argue that the latter may be regarded as a proxy for the full information forecast of inflation. Both measures are calculated as the sum of squared monthly changes of inflation from  $t - 1$  to  $t - 6$ . According to H2, if the variability of either actual inflation or professional forecasts increases, people should pay more attention to inflation and, thus, have an increased probability to update their expectations. Additionally, we test for an effect of

disagreement of professional forecasters, measured by the interquartile range indicating the dispersion of forecasts, and of the volatility of mean forecasts over all consumers on the propensity of individual consumers to update their inflation expectations.

Next, we attempt to evaluate hypothesis H3 from the rational inattention model by testing for the effect of news on individuals' updating behavior. The hypothesis H3 states that attention towards inflation should be a positive function of news regarding inflation, as these should lower the marginal cost of attention and, thus, increase the probability of an update. This is in line for instance with arguments in [Lamla and Sarferaz \(2012\)](#). We account for news effects by including the change in the number of news on inflation in the media over the last six months and the individual change between interviews in the variable stating whether the individual observed any news on inflation. We thus disentangle the sender and receiver perspective regarding the news. Additionally, we also account for possible asymmetries, e.g. that news heard on high inflation might be more likely to trigger an adjustment of expectations compared to news on low or falling inflation.

Finally, we test for evidence regarding hypothesis H4, which was derived from the model in [Dräger \(2011a\)](#). Under H4, the probability of updating inflation expectations should be positively affected by an increase in individuals' own past forecast errors, since the predictor formed with outdated information becomes less attractive, the higher its forecast error. We thus include the absolute individual forecast error from the first interview as an explanatory variable for the propensity to update expectations in the second interview. Notably, as we have only a six-months lag between both interviews, the forecast error from six months ago has not been fully realized yet. Nevertheless, we take it as a proxy for the individual forecast error twelve months ago.

Tables 3-10 comprise the estimation results for the probability of updating inflation expectations. The first set of results shows models including different measures for inflation volatility as well as individual absolute forecast errors as determinants. In a second set of tables, we test for the effects of different news variables. We furthermore report results for the qualitative and the quantitative updating frequency. All tables report marginal effects with robust standard errors and all models additionally include demographic controls and yearly time fixed effects. Our sample starts in 1987m10 for the regressions on one-year-ahead expectations. For the 5-10-year expectations, the sample starts in 1990m10, since the regular monthly sampling of this question starts there.<sup>12</sup>

In general, we find that the suggested explanatory variables can explain more of the short-run updating behavior than the long-run updating behavior. This is certainly in line with our expectations. Long-run expectations should be more related to fundamental factors that vary only little and are not sufficiently captured by our set of determinants.

Given these results, we concentrate more on the updating behavior of short-run inflation expectations. We find that an increase in the volatility of either actual inflation

---

<sup>12</sup>Results for the whole sample period are available from the authors upon request.

or mean consumers' forecasts significantly increases the probability of an update of individual qualitative inflation expectations. The volatility of professionals' forecasts also enters with a relatively high positive coefficient, but nevertheless remains insignificant. Generally, we thus find evidence in favor of H1 and, thus, in favor of rational inattention regarding inflation.

With regard to the hypothesis H3, we find that own past forecast errors from the first interview positively affect the probability of an expectations update in the second interview in all models, with highly significant coefficients. In line with H3, this implies that consumers' own forecast accuracy may be used as a signal regarding the benefit of an information update.

Finally, regarding the news measures, we find no news effect on the updating of quantitative short-run inflation expectations. However, there is a significantly negative effect of media news on the propensity to update qualitative short-run inflation expectations, while a change in good news regarding inflation perceived by the individual consumer seems to trigger an update. We thus find some tentative evidence in favor of H2, but also evidence that more media reports on inflation may lead to less, rather than more, attention towards inflation.

## 4.4 Explaining Individual Forecast Errors

After analyzing the factors that may trigger an updating of short-run and long-run expectations in the previous section, we next evaluate forecast errors calculated from one-year-ahead quantitative inflation expectations for those individuals.

Figure 3 presents a Boxplot of individual forecast errors. Over the estimation period starting in 1987m10, errors are about zero on average, with the exception of largely negative forecast errors at the start of the financial crisis in 2008, when actual and expected inflation moved temporarily in opposite directions.<sup>13</sup> Furthermore, individual forecast errors have slightly more mass on the negative side. This suggests that more individuals overestimated, rather than underestimated, inflation during the sample period.

Figure 3: Boxplot of Individual Forecast Errors

The results in the previous sections give evidence of information frictions affecting individuals' attentiveness towards inflation in line with the theoretical hypotheses H1-H4. However, the question remains whether more attentiveness towards inflation, resulting in a higher probability of updating inflation forecasts, also coincides with a higher forecast accuracy. Therefore, we next analyze how absolute forecast errors regarding inflation

<sup>13</sup>Forecast errors since 1987m10 have a mean of -0.572 and standard deviation of 3.418, with a minimum of -19.254 and a maximum of 7.703. Hence, on statistical grounds, given standard levels of confidence, this calculated mean is not different from zero.

change when short-run inflation expectations were updated between interviews, i.e. when no update occurred.

Table 11: Individual Changes in Absolute Forecast Errors Conditional on Updating

	Mean	Median	SD	Obs
All	-0.61	-0.11	4.14	24,385
short-run quant. updated	-0.85	-0.38	4.78	17,900
short-run quant. not updated	0.06	0.04	0.96	6,485
short-run qual. updated	-0.93	-0.37	4.33	9,176
short-run qual. not updated	-0.41	-0.03	4.02	15,209

Note: Summary statistics for the truncated sample from 1987m10-2011m11. SD denotes the standard errors and Obs the number of observations.

Table 11 presents summary statistics for the individual changes in absolute forecast errors between interviews. Including all observations, the statistics show that, on average, absolute forecast errors decrease between interviews. This suggests, that in our sample average quantitative inflation expectations are more accurate in the second interview compared to the first interview. However, when we distinguish between individuals that updated either their quantitative or their qualitative inflation expectations and those that did not update, the summary statistics suggest that absolute forecast errors decrease much more strongly after an update of inflation expectations. In the case of no update of quantitative inflation expectations, absolute forecast errors even increase in the second interview. Overall, these summary statistics give tentative evidence that, on average, an update of inflation expectations has a positive effect on the individual forecast accuracy regarding inflation.

In a second step, we test whether the determinants which are found to affect the probability of an update in the models of the previous section, also have an impact on the forecast accuracy in the event of an update.<sup>14</sup> We thus estimate models for the absolute forecast errors of those individuals that updated their qualitative short-run inflation expectations in the second interview.<sup>15</sup> Specifically, we are interested in the sign of the effect of macroeconomic determinants, i.e. whether changes in macroeconomic conditions improve forecast accuracy or whether they have a detrimental effect.

As in the previous sections, we choose the explanatory variables for our analysis in line with the implications of imperfect information models. Possible determinants of individual forecast errors thus include the variance of actual inflation and of professional

<sup>14</sup>Since we are interested in analyzing the effects of an update of inflation expectations on individual forecast accuracy and in line with our results in Table 11, we only present regression results for those individuals that updated their qualitative short-run expectations. Regression results for individuals that did not update differ from those presented here and are available from the authors upon request.

<sup>15</sup>We differentiate between the updating of qualitative forecasts, since these seem to indicate a more substantial adjustment of inflation expectations. Results for individuals that updated their quantitative short-run inflation expectations are available upon request.

forecasts. Additionally, we include the variance of mean short-run expectations by individual consumers and account for the dispersion of professional forecasts, measured by the interquartile range, as a proxy for uncertainty regarding inflation. Moreover, we test for the effect of news regarding inflation on consumers' forecast accuracy, again distinguishing between perceived news and those reported in the media. The lagged level of inflation is included in all regressions in order to capture macroeconomic level effects on forecast errors. Finally, we test whether individual forecasts are significantly affected by the business cycle, as put forward for instance in [Maćkowiak and Wiederholt \(2009\)](#), including a dummy for recessionary periods identified by the NBER.

Results from OLS regressions with robust standard errors are presented in [Tables 12 to 13](#). We employ lagged values for inflation, professionals' expectations and media news to account for publication lags and possible overlapping of professionals' and consumers' surveys. Furthermore, we account for individual and time-specific variation by incorporating demographic controls and year fixed-effects. Again, the estimation sample starts in 1987m10.<sup>16</sup>

Evaluating the absolute forecast errors of individuals that updated their qualitative inflation expectations, the results in [Table 12](#) suggest that a higher volatility of actual inflation improves the forecast accuracy of individuals. This result is in line with the theoretical implications of rational inattention in hypothesis H1, where a higher inflation volatility is associated with a higher degree of attentiveness towards inflation and, hence, a better forecast accuracy when expectations have been updated. Moreover, we find additional positive effects of the level of inflation on the forecast accuracy of individuals with updated expectations. Somewhat surprising, the interquartile range of professional forecasters is also found to reduce consumers' forecast errors. However, the effect of uncertainty regarding inflation might be captured by the "news heard"-dummy, since we find a positive effect of news heard regarding prices in the last model.

Regarding the effect of news about inflation on absolute forecast errors of individuals with updated qualitative inflation expectations in [Table 13](#), we find that news generally reduce the accuracy of individuals' inflation forecasts. This result is somewhat surprising, as news would be expected to contain relevant information on inflation and, thus, should increase forecast accuracy. While the coefficient on general news perceived by the individual is positive, albeit insignificant, we find a significantly positive effect of lagged media news on absolute forecast errors.

Disentangling the effect of perceived news on high versus low inflation or of favorable versus unfavorable news regarding inflation, we find that the adverse news effect on forecast accuracy is driven by bad news regarding inflation, i.e. news on high or rising inflation. By contrast, the coefficient on good news is negative, albeit insignificant. The overall negative news effect on forecast accuracy thus seems to be due to a dominance of negative news regarding inflation. The asymmetric media effects on consumers' inflation

---

<sup>16</sup>Results for the whole sample period are provided by the authors upon request.

Note: Robust standard errors are in parentheses. \*\*\*, \*\* and \* denote significance at the 1%, 5% and 10% level, respectively.  $\pi_{t-1}$  denotes the consumer inflation in the previous month,  $\sigma_{\pi^{e,prof},t-1}^2$  the volatility of professionals' 1-year-ahead inflation expectations.  $NBER\_recession_t$  is a dummy indicating that this period is an official recession period.  $Newsprices_t$  indicates whether individuals report any news heard on prices or inflation in the interview.  $Volume_{t-1}$  denotes the volume of media news on inflation in the last month.  $Newsprices\_high_t$ ,  $Newsprices\_low_t$ ,  $Newsprices\_bad_t$  and  $Newsprices\_good_t$  are dummy variables measuring whether news on rising and falling inflation are perceived and whether these news are favorable or not.

expectations and perceptions documented in [Lamla and Lein \(2008\)](#) and [Dräger \(2011b\)](#) for different European countries, thus also seem to play a role for individual consumers' expectations in the U.S.

## 4.5 The Role of Updates in Inflation Expectations for Explaining Bond Returns

In the previous section, we analyzed the impact of updating and its determinants on absolute forecast errors. Now we would like to know if updating behavior influences financial markets. For this purpose we investigate the effect of the share of people that have adjusted their inflation expectations on the absolute change of the term spread. We argue that if more people adjust their expectations, this must imply a stronger movement in the term spread. In a second step, we then evaluate the effect of updating on the absolute change in the spread between nominal and inflation indexed bond yields. A change in the absolute gap can only be explained by market microstructure effects and most importantly by changes in the assessment regarding inflation. If many people change their expectations, the adjustment should be stronger.

For this purpose we extract the treasury-bill constant maturity secondary market rate from the economic research data base at the Federal Reserve Bank at St. Louis (FRED). We use the term-spread between the one-year and the five-year maturity (See, e.g., [Fama and French, 1989](#)). Furthermore, we take the 5-year nominal bond yield and subtract the 5-year yield of the corresponding inflation indexed bond. For both measures we calculate the difference with respect to the previous six months and take absolute values.

Table 14 contains the regression results. Overall, we find evidence that changes in bond spreads are related to the share of people that have adjusted their expectations within six months. This implies that information rigidities diffuse into financial markets. In the first two columns we regress the updating share on the absolute change in the term spread of 1- to 5-year treasury bill rates. As expected, if more people adjust their short-run inflation expectations, this leads to a greater movement in the term spread. In the last two columns we regress the updating share of 5-10-years expectations on the absolute change of the difference between nominal yields and inflation indexed yields for 5-years treasury bills. Similar to the previous findings, a higher updating share in the longer-term expectations significantly affects the movement in the inflation premium.<sup>17</sup>

---

<sup>17</sup>As further robustness checks we run estimations with different term-spreads up to 20 years. Furthermore, we replicate the results using the data employed by [Welch and Goyal \(2008\)](#) which lead to qualitatively identical results. All results are available upon request.

Table 14: Absolute Changes in Term Spreads and Updating

	(1)	(2)	(3)	(4)
	$ \Delta_6(r^5 - r^1) $	$ \Delta_6(r^5 - r^1) $	$ \Delta_6(r_{nom}^5 - r_{real}^5) $	$ \Delta_6(r_{nom}^5 - r_{real}^5) $
1year	0.722** (0.310)			
1year qual.		0.011 (0.194)		
5-10 years			2.025** (0.846)	
5-10 years qual.				4.713*** (1.279)
Constant	-0.122 (0.230)	0.408*** (0.075)	-0.951* (0.578)	-0.387* (0.217)
Observations	286	286	101	101
Adj. $R^2$	0.018	0.000	0.039	0.163

Note: Bootstrapped standard errors in parenthesis. \*\*\*, \*\* and \* denote significance at the 1%, 5% and 10% level, respectively. 1year/1year qual. represents the share of people that changed their 1-year-ahead quantitative/qualitative expectations within six months. 5-10 year/5-10 year qual. represents the share of people that changed their 5-10-years-ahead quantitative/qualitative expectations within six months.  $|\Delta_6(r^5 - r^1)|$  is the absolute change over six months in the term spread between the 5-year treasury bill rate and the 1-year treasury bill rate at constant maturity.  $|\Delta_6(r_{nom}^5 - r_{real}^5)|$  represents the absolute change over six months in the spread between the 5-year nominal yield and the 5-year inflation indexed yield of the treasury bill at constant maturity.

## 5 Conclusion

Our study contributes to the understanding of the expectations formation process of consumers by providing evidence for individual consumers. Employing the rotating panel structure of the Michigan Survey of Consumers, we find evidence that the updating frequency based on quantitative short-run inflation expectations has been underestimated. In contrast, the qualitative assessment regarding inflation is adjusted less often, shows a cyclical pattern and is correlated with a more substantial revision in the quantitative assessment of the inflation outlook. Hence, people fine-tune their expectations quite regularly, but change their general assessment less often. Regarding the horizon of expectations, we find that long-term expectations are adjusted less frequently than short-run expectations.

We furthermore explore the relevance of potential determinants that may trigger an updating of inflation expectations and their impact on the forecast accuracy. Applying the test proposed by [Coibion and Gorodnichenko \(2010\)](#) we can confirm that information frictions seem to play an important role for short-run inflation expectations on an individ-

ual level. Becoming more specific regarding the determinants of attention we confirm that rising volatility of actual inflation is found to trigger an updating of consumers' expectations, suggesting that rational inattention may play a role in the expectation formation process. In addition, individuals' own forecast errors as well as perceived news on inflation are also relevant drivers of adjustments in consumers' inflation expectations.

With regard to the effect of information frictions on forecast accuracy, we find that an update of inflation expectations is related to a larger improvement in forecast accuracy. Moreover, individual forecast errors are affected by both the level and the variability of actual inflation, where higher levels improve the forecast accuracy of consumers in the event of an update, in line with predictions from rational inattention theories. However, news on inflation are found to reduce the accuracy of consumers' inflation expectations if expectations have been updated. This latter result is mostly driven by a detrimental effect of unfavorable news regarding inflation.

Our study thus lends support for models of imperfect information regarding the formation of inflation expectations. Furthermore, we show that the updating behavior of individuals varies over time and that there exist asymmetric effects, for instance regarding the perception of news on inflation. This suggests that not only information frictions, but also the content of the information, is important for the expectation formation process.

Finally, we provide evidence that updating behavior of consumers' has consequences for the evolution of term spreads in bonds markets. Specifically, a higher share of consumers that have adjusted their expectations is related to a larger change in the term spreads between 1-year and 5-years treasury bill rates but at the same time increase the spread between nominal and inflation indexed bonds. A more detailed analysis of these effects would certainly be warranted, and is left for future research.

Notes: *Obs* denotes the sample size, *SD* is the standard deviation while *Min* and *Max* represent the minimum and maximum values.

Figure A.1: Updating Shares for Inflation Expectations with Quant. Updates  $> 1\%$

(a) Short-run expectations, 1 year, update  $> 1\%$  (b) Short-run expectations, 1 year, qualitative answer

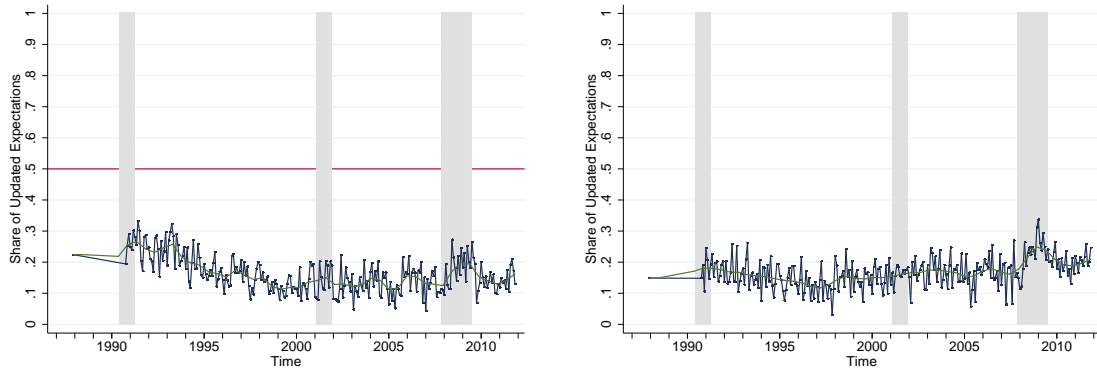

(c) Long-run expectations, 5-10 years, update  $> 1\%$  (d) Long-run expectations, 5-10 years, qualitative answer

Notes: The graphs show the share of individual consumers that change their inflation expectations within six months together with a smoothing polynomial trend. Shaded areas are recession phases as identified by the NBER. The share is calculated by taking all individuals that adjusted their expectations during the last six months and divide them by the overall number of individuals that have been re-interviewed.

Figure A.2: Updating Shares for Inflation Expectations with Quant. Updates  $> 5\%$

(a) Short-run expectations, 1 year, update  $> 5\%$  (b) Short-run expectations, 1 year, qualitative answer

(c) Long-run expectations, 5-10 years, update  $> 5\%$  (d) Long-run expectations, 5-10 years, qualitative answer

Notes: The graphs show the share of individual consumers that change their inflation expectations within six months together with a smoothing polynomial trend. Shaded areas are recession phases as identified by the NBER. The share is calculated by taking all individuals that adjusted their expectations during the last six months and divide them by the overall number of individuals that have been re-interviewed.
